Abstract

We investigate the Fermi Liquid theory of high density QCD. Using the renormalization group (RG), we determine the behavior of effective fermion interactions near the Fermi surface. At sufficiently high densities the matching between the Fermi Liquid theory and QCD can be accomplished in perturbation theory and a reliable calculation of Cooper pair formation performed, modulo the existence of a magnetic screening mass for the gluon. The presence of a chemical potential leads to different RG flows for sub-components of the effective interactions which would ordinarily be linked by Lorentz invariance. We also study instanton-induced operators and find that near the Fermi surface they are likely to be subdominant relative to operators induced by perturbative gluon exchange. We discuss the implications of our results for the phase structure of QCD at finite baryon density and temperature.

1 Introduction

In this paper we investigate the dynamics of quark excitations near the Fermi surface of high density QCD. Asymptotic freedom, as well as explicit calculations [1], suggest that the high density limit is controlled by a small coupling: α_s evaluated at the length scale of typical quark separation. However, it is well known that even very weak interactions can lead to interesting behavior in the presence of a Fermi surface [2]. In particular, pair formation leading to a mass gap, superfluidity and superconductivity seem generic whenever an attractive interaction, no matter how weak, is present. One way to understand this is through the Fermi Liquid theory originally developed by Landau, and recently clarified using the renormalization group (RG) [3]. We review the RG method in section 2 below within the context of relativistic theories. Our paper can be regarded as a first exploration of this method applied to ultra-relativistic, non-Abelian gauge theories. Here we simply note that Fermi Liquid theory can be regarded as an effective field theory of fermionic excitations, in which all interactions turn out to be irrelevant with the exception of four fermion vertices with the kinematic structure associated with Cooper pairing (i.e. – two quarks scattering with equal and opposite spatial momenta). The renormalization group flows of these special operators therefore determine the characteristics of the model.

At sufficiently high density we expect that the matching between the fermionic effective theory and QCD can be accomplished in perturbation theory (we discuss the details of this matching in section 3). The four fermion operators which are induced at leading order are simply those from one gluon exchange with an IR cut off provided by the gluonic screening masses. The gap equations resulting from one gluon exchange were studied in some detail by Bailin and Love [4]. As we will discuss in section 4, their results are qualitatively similar to ours in the high density regime, with the attractive $\bar{3}$ interaction leading to 0^+ or 0^- diquark condensation and color superconductivity. The RG approach provides an intuitive understanding of this result since it is the attractive $\bar{3}$ interaction between two left (right) handed quarks that flows first to a Landau pole as we approach the Fermi surface.

At somewhat lower densities, one might expect that non-perturbative interactions, such as those mediated by instantons, play a role in the Fermi Liquid theory. Recent attention [5] has focused on the effects of instanton-inspired fermionic models of QCD, although most of the analysis has been in the mean-field approximation, with quantum corrections neglected. In section 5 we study the combined RG flow of instanton and one-gluon induced vertices. We find that the one-gluon vertices grow much faster as the Fermi surface is approached. Therefore, unless the instanton vertices are larger than the one-gluon vertices at the matching scale (which seems implausible), the dynamics is probably controlled by one-gluon effects. This suggests that the high density phase identified above will persist to the (assumed)

boundary with the low density phase which exhibits chiral symmetry breaking.

Our paper is organized as follow. In section 2 we discuss the RG description of Fermi Liquid theory for relativistic systems. In section 3 we describe the matching conditions between QCD and our effective theory. In section 4 we derive and solve the RG equations governing the flow of gluonic four fermion operators, obtaining an expression for the condensate size as a function of quark density. In section 5 we study the combined RG equations for the instanton and gluonic operators, and find that the gluonic operators are dominant near the Fermi surface. In section 6 we discuss our results and their implications for QCD at high densities and temperatures.

2 Fermi Liquids from the Renormalization Group

We wish to study QCD at finite density, which is described by the following lagrangian with chemical potential μ

$$\mathcal{L} = -\frac{1}{4}F^{a\mu\nu}F_{\mu\nu}^a + \bar{\psi}_i(i\not{D} + \mu\gamma_0)\psi_i \quad . \quad (1)$$

We make a guess as to the form of the effective theory close to the Fermi surface; the obvious guess based on the dynamics of non-relativistic systems is that the theory is one of weakly interacting fermions: these are the dressed “quasi-particles” of solid state physics language. We will henceforth refer to these effective degrees of freedom as “quarks”, with the understanding that they may in fact be related to the bare quarks in a complicated way. Rather than treating the gluons as propagating degrees of freedom we will integrate them out leaving a potentially infinite sum over local, higher dimension fermion operators. The locality of these operators requires that gluons be screened at long-distances, presumably by effective electric and magnetic mass terms induced by the medium. We will address the matching between the high scale QCD dynamics and the four Fermi theory in section 3 but for the moment we assume the matching can be performed and proceed.

The Fermi surface in (1) naturally breaks the $O(3,1)$ invariance of space-time to $O(3)$ and furthermore picks out momenta of order μ . It is therefore natural to study the theory as we approach the Fermi surface in a Wilsonian sense. We parameterize four momenta in the following fashion

$$p^\mu = (p_0, \vec{p}) = (k_0, \vec{k} + \vec{l}) \quad (2)$$

where $\vec{k}$ lies on the Fermi surface and $\vec{l}$ is perpendicular to it. We study the Wilsonian effective theory of modes near the Fermi surface, with energy and momenta

$$|k_0|, |\vec{l}| < \Lambda \quad , \quad \Lambda \rightarrow 0 \quad . \quad (3)$$

While this type of RG scaling is somewhat unfamiliar, it actually corresponds to thinning out fermionic degrees of freedom according to their eigenvalues under the operator $i\cancel{\partial} + \mu\gamma_0$. It is easy to see that eigenspinors of this operator with eigenvalues $\lambda_n : |\lambda_n| < \Lambda$ correspond to states satisfying (3). Consider an eigenspinor of the form

$$\psi_p = u(E, \vec{p}) e^{i(p \cdot x - p_0 t)} \quad , \quad (4)$$

where $u(E, \vec{p})$ satisfies the usual momentum-space Dirac equation with $E = |\vec{p}| = |\vec{k} + \vec{l}| = \mu \pm \mathcal{O}(\Lambda)$, and $p_0 = \mathcal{O}(\Lambda)$. Then by direct substitution we see that ψ_p satisfies

$$(i\cancel{\partial} + \mu\gamma_0) \psi_k = \mathcal{O}(\Lambda) \quad . \quad (5)$$

Thus, the RG flow towards the Fermi surface just corresponds to taking the cutoff on eigenvalues of $i\cancel{\partial} + \mu\gamma_0$ to zero.

Which interactions are relevant operators in this limit? For our guess to make sense the kinetic term for the fermions must be invariant when we scale energies and momenta, $k_0 \rightarrow sk_0$ (or, $t \rightarrow t/s$), and $\vec{l} \rightarrow s\vec{l}$, with $s < 1$. We must be careful though to satisfy all the global symmetries of the theory. In particular, there is a spurious symmetry of (1) in which we treat μ as the temporal component of a fictitious $U(1)_B$ gauge boson. In other words, the combined transformations $\psi \rightarrow e^{i\theta t} \psi$ and $\mu \rightarrow \mu - \theta$ leave the lagrangian (1) invariant. From this, we deduce that derivatives acting on ψ may only enter the effective theory as $i\cancel{\partial} + \mu\gamma_0$. This requires the kinetic term of our effective theory to be of the form

$$\mathcal{S}_{eff} = \int dt d^3p \bar{\psi}_i^a \left((i\partial_t + \mu)\gamma_0 - \vec{p} \cdot \vec{\gamma} \right) \psi_i^a \quad (6)$$

In the Wilsonian RG scaling, we eliminate all modes with energy and momenta $|k_0|, |l| > \Lambda$, where Λ is our cutoff. As discussed above, on the remaining degrees of freedom the operator $(i\partial_t + \mu)\gamma_0 - \vec{p} \cdot \vec{\gamma} \sim \mathcal{O}(\Lambda)$ and therefore scales like s . We deduce that for (6) to remain invariant, ψ must scale as $s^{-1/2}$. The term representing the Fermi surface scales as s^{-1} indicating that it is a relevant operator and that hence the existence of the surface is natural. Now consider the four fermion operator

$$iG \int dt d^3\vec{p}_1 d^3\vec{p}_2 d^3\vec{p}_3 d^3\vec{p}_4 \bar{\psi}_k \Gamma_{ki}^\mu \psi_i \bar{\psi}_l \Gamma_{lj} \psi_j \quad (7)$$

where Γ contains any gamma matrix and flavor or color structure. Naively, (7) is irrelevant since it scales as s if we assume we have $\vec{l}$ close to zero and hence

$$\delta^3(\vec{p}_1 + \vec{p}_2 - \vec{p}_3 - \vec{p}_4) \simeq \delta^3(\vec{k}_1 + \vec{k}_2 - \vec{k}_3 - \vec{k}_4) \quad , \quad (8)$$

which does not scale. Higher dimension terms with extra powers of the fields or terms with additional derivatives are clearly irrelevant operators as well. (Again, because of the spurious

symmetry higher derivative terms must enter in combination with μ , and hence scale like s .) The only operators that survive are those satisfying the kinematic constraint $\vec{p}_1 \simeq -\vec{p}_2$, so the delta function becomes

$$\delta(\vec{l}_1 + \vec{l}_2 - \vec{l}_3 - \vec{l}_4) \quad (9)$$

and scales as s^{-1} ($\int dl \delta(l) = 1$). The resulting four fermion operator is marginal.

The only interactions in the effective theory are therefore four fermion operators at a special kinematic point, and the model is exactly soluble by resummation. The only diagrams allowed by the momentum structure are the bubble diagrams found at large N in the familiar $O(N)$ model. The interaction generates cooper pair formation through the gap equation (see Bailin and Love in [4])

$$\Delta = iG \int_0^{\Lambda_{UV}} \frac{d^4 p}{(2\pi)^4} \Gamma^\mu C(p) \Gamma_\mu \quad , \quad (10)$$

where G is the coupling, Γ^μ any associated Dirac structure and $C(k)$ a 4×4 off diagonal component of the 8×8 propagator associated with the fermion vector (ψ, ψ^C)

$$C(p) = \frac{1}{(\not{p} - \mu\gamma_0)} \Delta \frac{1}{[\tilde{\Delta}(\not{p} - \mu\gamma_0)^{-1} \Delta - (\not{p} + \mu\gamma_0)]} \quad (11)$$

where $\tilde{\Delta} = \gamma_0 \Delta^\dagger \gamma_0$. The gap integral would diverge logarithmically as $p_0 \rightarrow 0$ and $|\vec{p}|^2 \rightarrow \mu^2$, were it not for the factors of Δ in the denominator of $C(p)$ which provide an IR cutoff. Ignoring the Lorentz structure of the integral for the moment, we have

$$\Delta \sim -iG \int_\Delta^{\Lambda_{UV}} \frac{d^4 p}{(2\pi)^4} \frac{1}{(\not{p} - \mu\gamma_0)} \Delta \frac{1}{(\not{p} + \mu\gamma_0)} \quad , \quad (12)$$

or,

$$\Delta \sim \frac{-iG\Delta}{4} \int_\Delta^{\Lambda_{UV}} \frac{d^2 k \, dl \, dk_0}{(2\pi)^4} \frac{1}{(k_0 + l - i\epsilon)(k_0 - l + i\epsilon)} \quad (13)$$

$$\sim \frac{GN\Delta}{4} \ln\left(\frac{\Lambda_{UV}}{\Delta}\right) \quad . \quad (14)$$

Here $N = \int d^2 k / (2\pi)^3 = \mu^2 / 2\pi^2$ is the density of states at the Fermi surface in the lowest order approximation. The Cooper pair condensate is of the form

$$\Delta = \Lambda_{UV} e^{-\frac{c}{G}} \quad , \quad (15)$$

where c is a constant.

Thus we obtain the result (well known in the context of non-relativistic superconductivity) that any weakly attractive operator of this form generates cooper pair formation. A repulsive interaction ($G < 0$) only has the consistent solution $\Delta = 0$. This conclusion in the relativistic case depends on the precise Lorentz matrix structure of the interaction and the

condensate and is the subject of study below. Although the condensate appears to be formed due to weak interactions this is a misleading consequence of the exact solubility of the gap equation. In fact as we will show in section 4 the couplings become strong as the effective theory approaches the Fermi surface, and from this point of view it is the strong coupling physics that generates the condensate. By analogy, if one could solve the Swinger-Dyson equations of zero density QCD at short distance, where the coupling is small, one might incorrectly conclude that the usual chiral condensate results from weak coupling effects, while it is in fact due to strong IR effects.

To determine the behavior of QCD at high density we must first perform the matching between QCD and the four Fermi theory (section 3). We will see that several types of four fermion interaction are generated. In section 4 we will perform a RG analysis of how those couplings run to the Fermi surface to identify the dominant attractive interaction.

3 Matching to QCD

At very high density, $\mu \gg \Lambda_{QCD}$, we expect the four quark coupling to be dominated by one gluon exchange due to asymptotic freedom. By taking μ sufficiently large $g(\mu)$ can be made arbitrarily small and one loop effects are then negligible. At tree level QCD generates several four fermion vertices. A pair of quarks in the 6 representation of $SU(3)$ can scatter to a 6, and quarks in the $\bar{3}$ can scatter to the $\bar{3}$. However, the 6 and $\bar{3}$ can not mix. In addition because the introduction of μ breaks the $O(3,1)$ invariance of the theory we must treat the temporal and spatial components of the couplings independently. We thus have four interactions in the four fermi theory:

$$\begin{aligned}
& iG_6^0 (\delta_{ca}\delta_{db} + \delta_{cb}\delta_{da}) \bar{\psi}_c \gamma_0 \psi_a \bar{\psi}_d \gamma_0 \psi_b \\
& iG_6^i (\delta_{ca}\delta_{db} + \delta_{cb}\delta_{da}) \bar{\psi}_c \gamma_i \psi_a \bar{\psi}_d \gamma_i \psi_b \\
& iG_3^0 (\delta_{ca}\delta_{db} - \delta_{cb}\delta_{da}) \bar{\psi}_c \gamma_0 \psi_a \bar{\psi}_d \gamma_0 \psi_b \\
& iG_3^i (\delta_{ca}\delta_{db} - \delta_{cb}\delta_{da}) \bar{\psi}_c \gamma_i \psi_a \bar{\psi}_d \gamma_i \psi_b
\end{aligned} \tag{16}$$

where we have used the decomposition

$$(T^a)_{ca}(T^a)_{db} = \frac{1}{6}(\delta_{ca}\delta_{db} + \delta_{cb}\delta_{da}) - \frac{1}{3}(\delta_{ca}\delta_{db} - \delta_{cb}\delta_{da}) \quad . \tag{17}$$

Henceforth we will include signs from the contraction of spacelike γ_i matrices in the coupling constants. The one-gluon approximation yields the following matching conditions:

$$\begin{aligned} G_6^0 &= \frac{1}{6} \frac{4\pi\alpha_s}{k^2} & G_3^0 &= -\frac{1}{3} \frac{4\pi\alpha_s}{k^2} \\ G_6^i &= -\frac{1}{6} \frac{4\pi\alpha_s}{k^2} & G_3^i &= \frac{1}{3} \frac{4\pi\alpha_s}{k^2} \end{aligned} \quad , \quad (18)$$

where k is the four-momentum in the gluon propagator.

However, this is too naive and leads to non-local interactions dominated by arbitrarily soft gluon exchange ($k \rightarrow 0$), with all the consequences of asymptotic freedom. It is reasonable to assume that the non-zero quark density screens long-range gluon exchange, leading to an effective gluon “mass”. At one loop order, a chemical potential leads to Debye screening of the temporal component of the gluon that can be calculated perturbatively [1]. The details are not important here, but the result is of the form

$$M_0^2 \sim g^2 \mu^2 \quad . \quad (19)$$

It is generally believed that the spatial or magnetic components of the gluons acquire masses only non-perturbatively. If the finite density behavior is similar to the finite temperature case, one would expect

$$M_i^2 \sim g^4 \mu^2 \quad . \quad (20)$$

In this paper we merely assume the existence of both a magnetic and electric screening mass, with the electric mass somewhat larger. Our results will be qualitatively independent of the precise values of these masses, which provide a cutoff on infrared effects. In the four fermion theory we therefore introduce a form factor

$$\frac{ig^2}{(k^2 - M_{0,i}^2)} = \frac{-ig^2}{M_{0,i}^2} \left(\frac{1}{1 + k^2/M_{0,i}^2} \right) = \frac{-ig^2}{M_{0,i}^2} \left(1 - \frac{k^2}{M_{0,i}^2} + \dots \right) \quad . \quad (21)$$

Since $k_0 \rightarrow 0$ as we approach the Fermi surface, $k^2 < 0$, and the largest interactions come from scatterings with small momentum transfer. In fact, our previous arguments concerning the spurious $U(1)_B$ symmetry imply that the higher order terms in this expansion are suppressed (correspond to irrelevant operators) near the Fermi surface. Hence in the $s \rightarrow 0$ limit we need only retain interactions with constant form factor (no derivatives) in our RG analysis. In the BCS analysis [2] a constant potential is also used, and this is usually regarded as a crude approximation. However, the symmetry argument implies that it is accurate near the Fermi surface. Note that the symmetry argument does *not* imply that the k^2/M^2 terms can be neglected at the matching scale. Indeed, one can easily see that neglecting the higher order terms on the r.h.s. of (21) leads to a large overestimate of the strength of the interaction. Note that we have performed the matching in Feynman gauge. In the one loop approximation results such as the location of the Landau pole are gauge invariant, so we

can make any choice of gauge. However, some gauge dependence may arise from the gluon masses, which we have inserted by hand.

In order to obtain an accurate matching of a four fermion operator with constant form factor to the one-gluon interaction, we average the momentum dependent function in (21) over all incoming and outgoing quark momenta, with both quarks near the Fermi surface. This is equivalent to projecting out the zero angular momentum component of the operator. It is possible to separate any operator into eigenstates of angular momentum, which do not mix under the RG flow. Since we expect that the eventual condensate will be in the zero angular momentum channel (see [4] for a careful justification of this in the case of the one-gluon exchange kernel), we do not lose any information by only retaining this component. Let $\vec{p}$ and $\vec{q}$ denote the incoming and outgoing momenta of a quark line, and

$$k^2 = (p - q)^2 = p^2 + q^2 - 2p \cdot q \quad . \quad (22)$$

For $\vec{p}$ and $\vec{q}$ near the Fermi surface, and θ the angle between $\vec{p}$ and $\vec{q}$, this becomes

$$k^2 = -2\mu^2(1 - \cos \theta) \quad . \quad (23)$$

Averaging the form factor (21) over all relative orientations of $\vec{p}$ and $\vec{q}$, we obtain

$$\begin{aligned} \frac{1}{4\pi\mu^2} \int d^2k \frac{1}{k^2 - M^2} &= \frac{1}{4\mu^2} \int_{-1}^{+1} dz \frac{1}{1 - z + M^2/2\mu^2} \\ &= \frac{1}{4\mu^2} \ln \left[\frac{4\mu^2}{M^2} \right] \quad . \end{aligned} \quad (24)$$

We see that in this approximation the matching conditions depend only logarithmically on the gluon masses $M_{0,i}$. A more sophisticated scheme for estimating the strength of the constant form factor of the four fermion interaction might yield a slightly different relation than (24), but we expect it to still depend only weakly on the screening masses. The logarithm in (24) is of order $\ln[g^{-2}]$ or $\ln[g^{-4}]$, and is somewhat larger than one.

Our matching conditions are then:

$$\begin{aligned} G_6^0 &= -\frac{1}{6} \frac{\pi\alpha_s(\mu)}{\mu^2} \ln \left[\frac{4\mu^2}{M^2} \right] & G_3^0 &= \frac{1}{3} \frac{\pi\alpha_s(\mu)}{\mu^2} \ln \left[\frac{4\mu^2}{M^2} \right] \\ G_6^i &= \frac{1}{6} \frac{\pi\alpha_s(\mu)}{\mu^2} \ln \left[\frac{4\mu^2}{M^2} \right] & G_3^i &= -\frac{1}{3} \frac{\pi\alpha_s(\mu)}{\mu^2} \ln \left[\frac{4\mu^2}{M^2} \right] \quad . \end{aligned} \quad (25)$$

The scale of this matching is of order μ , and corresponds to the typical momentum transfer in the scattering of two quarks on the Fermi surface.

Figure 1: One loop diagram from gluon exchange which drives the RG flow of effective four fermion interactions.

4 One Gluon RG Flow

The Fermi liquid displays interesting behavior such as superconductivity because in the effective theory the marginal four fermion interactions flow to strong coupling as they approach the Fermi surface. To display the basic behavior, consider a theory with just the simple interaction

$$iG\bar{\psi}\psi\bar{\psi}\psi \quad . \quad (26)$$

This interaction leads to a one loop graph which is the analog of figure 1 with the gluon lines contracted. (Note that because of the restricted momentum structure of the vertices in the effective theory the diagram with crossed gluon lines has no counterpart and does not play a role in the RG flow.) It contributes a logarithmic divergence to the running in the presence of a Fermi surface:

$$-G^2 \int \frac{d^4p}{(2\pi)^4} \left[\frac{i}{p^\mu \gamma_\mu + \mu \gamma_0 - i\epsilon} \right]_{ik} \left[\frac{i}{-p^\nu \gamma_\nu + \mu \gamma_0 - i\epsilon} \right]_{jl} \quad (27)$$

Performing the gamma matrix algebra and taking the limit $k_0, |\vec{l}| \rightarrow 0, |\vec{k}|^2 \rightarrow \mu^2$, this becomes

$$G^2 \left[-(\gamma_0)_{ij}(\gamma_0)_{kl} + \frac{1}{3}(\gamma_\alpha)_{ij}(\gamma_\alpha)_{kl} \right] I \quad (28)$$

where the log divergent part of the integral I is given by

$$I = \frac{1}{4} \int \frac{dk_0 d^2k dl}{(2\pi)^4} \frac{1}{(k_0 + l - i\epsilon)(k_0 - l + i\epsilon)}$$

$$\simeq \frac{i}{4} N \ln \left(\frac{\Lambda_{IR}}{\Lambda_{UV}} \right) \quad . \quad (29)$$

$N = \int d^2k / (2\pi)^3 = \mu^2 / 2\pi^2$ is the density of states at the Fermi surface in the lowest order approximation. Here we have moved from an effective theory with cutoff Λ_{UV} ($k_0, |\vec{l}| < \Lambda_{UV}$), to a new effective theory with cutoff Λ_{IR} . As we approach the Fermi surface ($\Lambda_{IR} \rightarrow 0$), the coupling G runs logarithmically.

In this fashion we can calculate the one loop beta functions for the vertices in (16) as a function of $t = \ln(\Lambda_{IR}/\Lambda_{UV})$. It is most convenient to perform the calculation (in the massless limit) using two component Weyl spinors. The gluon exchange conserves helicity and flavor quantum numbers. From figure 1 and (28) it can be seen that the graphs, in two component notation, involve the contractions of 6 sigma matrices (associated with the gauge vertices and resulting from the loop integral). The following σ matrix identities are useful

$$(\sigma^i)_{ab}(\sigma^j)_{bc}(\sigma^k)_{cd}(\sigma^i)_{xy}(\sigma^j)_{yz}(\sigma^k)_{zw} = 7(\sigma^i)_{ad}(\sigma^i)_{xw} - 6(\sigma^0)_{ad}(\sigma^0)_{xw} \quad (30)$$

$$(\sigma^i)_{ab}(\sigma^j)_{bc}(\sigma^0)_{cd}(\sigma^i)_{xy}(\sigma^j)_{yz}(\sigma^0)_{zw} = -2(\sigma^i)_{ad}(\sigma^i)_{xw} + 3(\sigma^0)_{ad}(\sigma^0)_{xw} \quad (31)$$

$$(\sigma^i)_{ab}(\sigma^0)_{bc}(\sigma^0)_{cd}(\sigma^i)_{xy}(\sigma^0)_{yz}(\sigma^0)_{zw} = (\sigma^i)_{ad}(\sigma^i)_{xw} \quad (32)$$

$$(\sigma^0)_{ab}(\sigma^0)_{bc}(\sigma^0)_{cd}(\sigma^0)_{xy}(\sigma^0)_{yz}(\sigma^0)_{zw} = (\sigma^0)_{ad}(\sigma^0)_{xw} \quad (33)$$

The gamma matrix algebra at one loop distinguishes the couplings between two left (right) handed quarks and those between left and right handed quarks. This is a result of the divergence in the diagram of figure 1. Without a chemical potential this diagram is not divergent for the restricted shell of momenta under consideration, and this discrepancy between the two interactions is not seen. The RG eqns are

$$\frac{dG_{aLL}^0}{dt} = \frac{N}{2} \left(-(G_{aLL}^0)^2 + 2G_{aLL}^0 G_{aLL}^i - 5(G_{aLL}^i)^2 \right) \quad (34)$$

$$\frac{dG_{aLL}^i}{dt} = \frac{N}{2} \left(\frac{1}{3}(G_{aLL}^0)^2 - \frac{10}{3}G_{aLL}^0 G_{aLL}^i + \frac{13}{3}(G_{aLL}^i)^2 \right) \quad (35)$$

$$\frac{dG_{aLR}^0}{dt} = \frac{N}{2} \left(-(G_{aLR}^0)^2 + 2G_{aLR}^0 G_{aLR}^i - (G_{aLR}^i)^2 \right) \quad (36)$$

$$\frac{dG_{aLR}^i}{dt} = \frac{N}{2} \left(\frac{1}{3}(G_{aLR}^0)^2 - \frac{2}{3}G_{aLR}^0 G_{aLR}^i + \frac{1}{3}(G_{aLR}^i)^2 \right) \quad . \quad (37)$$

We suppress the RR and RL equations since they are respectively identical to the LL and LR equations already displayed. The a subscript corresponds to either 6 or $\bar{3}$; note that again loop effects do not mix the two channels.

These equations diagonalize to

$$\frac{d(G_{aLL}^0 + G_{aLL}^i)}{dt} = -\frac{1}{3}N(G_{aLL}^0 + G_{aLL}^i)^2 \quad (38)$$

$$\frac{d(G_{aLL}^0 - 3G_{aLL}^i)}{dt} = -N(G_{aLL}^0 - 3G_{aLL}^i)^2 \quad (39)$$

$$\frac{d(G_{aLR}^0 + 3G_{aLR}^i)}{dt} = 0 \quad (40)$$

$$\frac{d(G_{aLR}^0 - G_{aLR}^i)}{dt} = -\frac{2}{3}N(G_{aLR}^0 - G_{aLR}^i)^2 \quad (41)$$

Taking $G^0 = G(0)$ and $G^i = -xG(0)$ as the boundary condition at $t = 0$, we obtain the solutions

$$G_{aLL}^0(t) = \frac{1}{4} \left(\frac{3G(0)(1-x)}{1 + \frac{N}{3}G(0)(1-x)t} + \frac{G(0)(1+3x)}{1 + NG(0)(1+3x)t} \right) \quad (42)$$

$$G_{aLL}^i(t) = \frac{1}{4} \left(\frac{G(0)(1-x)}{1 + \frac{N}{3}G(0)(1-x)t} - \frac{G(0)(1+3x)}{1 + NG(0)(1+3x)t} \right) \quad (43)$$

$$G_{aLR}^0(t) = \frac{1}{4} \left(G(0)(1-3x) + \frac{3G(0)(1+x)}{1 + \frac{2N}{3}G(0)(1+x)t} \right) \quad (44)$$

$$G_{aLR}^i(t) = \frac{1}{4} \left(G(0)(1-3x) - \frac{G(0)(1+x)}{1 + \frac{2N}{3}G(0)(1+x)t} \right) \quad (45)$$

We may now consider the boundary conditions from section 3. We expect $x > 1$, since the Debye mass appears at lowest order in perturbation theory and the magnetic mass is a higher-order (non-perturbative) effect. The Fermi surface lies at $t \rightarrow -\infty$. In the the $\bar{3}$ channel $G_{\bar{3}}(0)$ is positive and the LL (and RR) couplings have a Landau pole at

$$t = -1/NG_{\bar{3}}(0)(1+3x) \quad , \quad (46)$$

satisfying the asymptotic relation $G_{\bar{3}LL}^0 = -G_{\bar{3}LL}^i$. The LR (and RL) couplings also have a Landau pole at $t = -3/2NG_{\bar{3}}(0)(1+x)$ but this lies closer to the Fermi surface than the LL coupling pole for all $x > 1$. As we approach the pole in the LL (and RR) channel the LR (and RL) coupling becomes negligible in comparison.

In the 6 channel $G_6(0)$ is negative and smaller than $G_{\bar{3}}(0)$. The interaction remains repulsive and the LL (and RR) couplings have a Landau pole at $t = -1/3NG_6(0)(x-1)$. The LR couplings flow to constant values as the Fermi surface is approached.

We conclude that the Cooper pairing dynamics is dominated by the attractive $\bar{3}$ interaction between two left (right) handed quarks. The condensate that forms is therefore

antisymmetric in color. The LL and RR channels correspond to the antisymmetric spin 0 state and the condensate is either $\psi^T C \psi$ or $\psi^T C \gamma_5 \psi$. The one gluon exchange diagrams do not distinguish between the scalar and pseudo-scalar condensates, because the two are related by the $U(1)_A$ symmetry which at the level of one gluon exchange is a good symmetry. The dynamics is flavor blind but the flavor of the condensate is determined by Fermi statistics. It must be in the anti-symmetric singlet of flavor in the case of two light quarks. In the case of three light quarks there is the possibility of color-flavor locking [6]. In reality we expect the large strange quark mass to displace its Fermi surface relative to that of the up and down quarks. This mismatch of Fermi momenta disfavors mixed strange – nonstrange condensates, except possibly at lower densities where the condensate might be quite large. The mismatch in Fermi momenta is roughly

$$\Delta p_F = p_F - p_{Fs} = \mu - \sqrt{\mu^2 - m_s^2} \quad , \quad (47)$$

where μ is the common chemical potential for the u,d and s quarks. This will be relevant when the condensates are of order or less than Δp_F . For $\mu = 300$ MeV and $m_s = 150$ MeV, $\Delta p_F \simeq 40$ MeV. In the absence of mixed condensates the strange quarks will condense on their own in the $\bar{3}$ channel which is antisymmetric in color. There is only a flavor symmetric state available in this case. Thus the LL (RR) interaction can only cause the condensation of the antisymmetric spin 0 and angular momentum $L = 1$ state which would be smaller than the u and d condensate. There is also potentially competition from the LR (RL) couplings which have a Landau pole closer to the Fermi surface and could give rise to condensation in the symmetric spin 1 and $L = 0$ state. Again this condensate, if it formed, would be smaller than that in the u and d sector.

We are now in a position to estimate the size of the actual condensate, by computing the RG invariant scale (location of the Landau pole (46)) at which the $\bar{3}$, LL coupling diverges. This yields

$$\Delta = \Lambda_{UV} \exp \left(- \frac{1}{NG_{\bar{3}}(0) (1 + 3x)} \right) \quad . \quad (48)$$

Using the matching conditions from section 3, and the free-quark approximation to the density of states N , we have

$$\Delta = \Lambda_{UV} \exp \left(- \frac{6\pi}{1 + 3x} \frac{1}{\alpha_s} \ln \left[\frac{4\mu^2}{M_i^2} \right]^{-1} \right) \quad . \quad (49)$$

Note that for densities just above the expected phase boundary for chiral symmetry restoration, $\alpha_s \sim \mathcal{O}(1)$, and (49) predicts a relatively large condensate. As we increase the density, the condensate decreases. In order to compute the rate of decrease, we use the QCD beta function relation

$$\Lambda_{QCD} = \Lambda_{UV} \exp \left(- \frac{2\pi}{b_0} \frac{1}{\alpha_s(\Lambda_{UV})} \right) \quad , \quad (50)$$

where $b_0 = 11 - 2N/3$ for N flavors. Rewriting (49) in terms of Λ_{QCD} , we find

$$\frac{\Delta}{\Lambda_{QCD}} = \left(\frac{\Lambda_{QCD}}{\Lambda_{UV}} \right)^q, \quad (51)$$

where

$$q = \frac{3}{1 + 3x} \frac{b_0}{\ln[\frac{4\mu^2}{M_i^2}]} - 1.$$

Recalling that $\Lambda_{UV} \sim \mu$, we see that the condensate scale Δ decreases rapidly with increasing μ . Incidentally, equation (51) again shows that the system can naturally support $\Delta \sim \Lambda_{QCD}$, since at low density we expect $\Lambda_{UV} \sim \Lambda_{QCD}$. We have checked that our results in (49) and (51) are qualitatively consistent with the earlier gap equation calculations of [4] and [5].

Finally, we note that (49) actually predicts that the condensate will eventually increase at asymptotically high densities, due to the logarithm in the exponent. It is not clear how reliable this prediction is, as it depends sensitively on the matching (averaging) procedure and on the precise form of the magnetic screening mass M_i .

Figure 2: The gluonic correction to the instanton induced vertex.

5 Instanton RG Flow

Recently a number of groups [5] have considered the possible role of instanton induced interactions in color superconductivity, particularly at low densities. In this section we study the combined RG flow of instanton and gluon-induced interactions. At sufficiently

high density, instanton effects are almost certainly negligible. As we lower the density, the relative size of the instanton-induced operators at the matching scale should grow relative to the gluon operators. At sufficiently low densities we can imagine that the two types of interactions become roughly comparable in strength. The RG equations will tell us which interactions dominate the dynamics at the Fermi surface.

In the two-flavor case, which we analyse here, the instanton-induced operators are of the form

$$\kappa T^a T^a \left(\bar{u}_R u_L \bar{d}_R d_L - \bar{u}_R d_L \bar{d}_R u_L \right) \quad . \quad (52)$$

We assume that at the matching scale the instanton-induced coupling $\kappa(0)$ is smaller than the gluon-induced coupling $G(0)$. If this hierarchy persists as $t \rightarrow -\infty$, then it is self-consistent to neglect loop diagrams with multiple instanton vertices. In this case the RG flow of κ is determined by the effective field theory counterpart of the diagram in fig 2, which depicts the instanton operator renormalized by gluon exchange. In the effective theory we compute the loop diagrams with one gluon and one instanton type vertex. We obtain the following one loop beta functions, where again the subscript a denotes either the 6 or $\bar{3}$ channels.

$$\frac{d\kappa_a}{dt} = N\kappa_a(-G_{aLL}^0 + G_{aLL}^i) \quad . \quad (53)$$

Solving (53), we can directly compare the size of κ_a to $G_{\bar{3}LL}^0$ (the largest gluonic coupling). We find

$$\frac{\kappa_a(t)}{G_{\bar{3}LL}^0(t)} = \frac{\kappa_a(0)}{G_{\bar{3}LL}^0(0)} \frac{4}{(1+3x)} (1 + NG(0)(1+3x) t)^{1/2} \quad , \quad (54)$$

which shows that as we approach the Fermi surface the instanton interaction becomes more and more suppressed relative to the gluonic operator. When the gluonic $\bar{3}$ interaction reaches its Landau pole at $t = -1/NG(0)(1+3x)$, the instanton interaction is completely negligible. This result implies that as long as the instanton interaction is somewhat smaller than the gluon interaction at matching, the pattern of condensation will be determined solely by gluonic effects.

The diagram in figure 2 also induces operators with different Lorentz structure from the bare vertices, as do graphs with multiple instanton vertices. For example, an interaction of the form $(\bar{q}_R \gamma_0 \gamma_i q_L)(\bar{q}_R \gamma_0 \gamma_i q_L)$ is induced. The ratio of this new coupling to $G_{\bar{3}LL}^0$ behaves similarly to (54) and thus vanishes as one approaches the Fermi surface. In general, new vertices are always smaller than the bare couplings if we take $\kappa(0)$ somewhat less than $G(0)$. However, if $\kappa(0)$ and $G(0)$ are of the same size, as is possibly the case at lower densities, then the RG equations become considerably more complicated and the instanton vertex may play a role in Cooper pair formation.

6 Discussion

The renormalization group provides a powerful tool for the analysis of QCD at large quark density. The highly constrained nature of the effective field theory describing quarks near the Fermi surface allows a detailed analysis of the relevant interactions. We find that the operators induced by gluon exchange lead to Cooper pair (diquark) condensation and color superconductivity in the $\bar{3}$, $0^\pm$ channels. The relevant order parameter for the two-flavor condensate is

$$\psi_{ia}^T(-p) C (\cos(\theta) + i \sin(\theta) \gamma_5) \psi_{jb}(p) \epsilon^{ij} \epsilon^{abc} , \quad (55)$$

where C is the charge-conjugation matrix, (i,j) are flavor indices running from 1 to 2, and (a,b) are color indices. $\theta = \pi/2$ preserves parity, while other values break it spontaneously. Since the different θ condensates are related by the $U(1)_A$ symmetry, which is good to all orders in perturbation theory, the gluon interactions cannot differentiate between the two possibilities, and it is up to interactions like instantons to determine whether parity is violated [5]. At high densities, where instanton effects are negligible, explicit quark masses also violate the $U(1)_A$ symmetry, and we have checked that the parity conserving vacuum is the true minimum. Nevertheless, at high density the entire family of parity violating and parity conserving vacua are nearly degenerate. This implies the existence of a light pseudo-Goldstone boson analogous to the η' , except that it corresponds to rotations in the diquark condensate rather than the usual quark condensate. This particle is a color singlet, pseudo-scalar. Due to this excitation the mass gap in the physical spectrum can be much smaller than the condensate scale Δ .

Our calculations were performed assuming a sufficiently high density to justify perturbative matching to QCD. Strictly speaking, they should only be applied at densities somewhat larger than the critical density where the chiral phase transition is expected to occur. Nevertheless, they yield results which can be naively extrapolated to lower densities. Equation (51) suggests that a condensate of order Λ_{QCD} is possible.

We also studied instanton induced operators in the effective theory. We found that the RG flow of such operators is slower than that of the one gluon operators, and hence that the latter reach their Landau pole first. This lends further confidence that the one gluon results can be extrapolated to lower densities. However, it is still possible that non-perturbative effects affect diquark condensation, depending on the relative sizes of instanton and gluon operators at the matching scale.

Finally, we note that all of our calculations have been at zero temperature. A nonzero temperature would smear out the Fermi surface, eventually eliminating the condensates. Bailin and Love [4] studied the phase transition between the superconducting and normal

states in the one gluon exchange approximation, and found a fluctuation-induced first order phase transition. Since our results support the dominance of gluonic effects, they also suggest that the phase boundary is likely to be first order.

The authors would like to thank Christina Manuel, Rob Pisarski, Krishna Rajagopal, Ramamurti Shankar and Thomas Schaefer for useful discussions and comments. NE and MS would like to thank the Aspen Center for Physics for their hospitality while this work was completed.
